(54) Title: A METHOD OF PROCESSING AN ARTICLE BY MEANS OF A LASER BEAM

(57) Abstract

By a method of processing one or more articles by means of a pulsed laser beam, whereby the processing is performed in several steps, the laser beam is relatively displaced relative to the article after completion of each processing step so as to perform a processing step in a following processing area, whereby the sequence is repeated until the processing has been completed.

Title: A method of processing an article by means of a laser beam

Technical Field

The invention relates to a method of processing one or more articles by means of a pulsed laser beam, whereby the processing is performed in several steps.

Background Art

Laser processing by means of continuous or pulsed lasers is known. Furthermore it is common knowledge to drill holes by means of laser, where either one pulse or a number of pulses are used per hole, said holes being completed one by one, cf. German Offenlegungsschrift No. 2,719,275. The latter process is used for engraving pressure cylinders, whereby a hole or a recess is completed before the laser beam is directed towards another area so as to produce the next hole.

Disclosure of the Invention

The object of the present invention is to show how the quality of the processing can be improved without involving a substantially prolonged processing period.

According to the invention a pulse interval is selected for each processing which is extremely long compared to the pulse width. Typical pulse intervals are 1,000 times longer than the pulse width, and simultaneously the pulses are selected in a suitable pulse width interval, typically 0.02-0.1 ms, which is unusually short as far as CO<sub>2</sub> drilling lasers and other conventional drilling lasers are concerned. As a result it is possible to achieve an otherwise unachievable hole quality. The latter is due to the fact that the removal of material during each pulse is

insignificant, and the amount of plasma above in the hole is reduced which in turn substantially reduces the undesired formation of fuse in and around the hole. At the same time the plasma and the metal vapours disappear from the hole and the area between the laser beam and the hole before the successive pulse hits the article. In this manner holes are achieved which compared to previously are more cylindrical and contain less resolidified fuse on the walls of the hole. As a result it is possible to produce holes typically of a diameter and depth of

metal: diameter: 0.08-0.15 mm; depth: 1.0 mm

polycarbonate: diameter: 0.2 mm; depth 3.00 mm.

When several holes are drilled simultaneously during a continuous movement of the surface of the article relative to the laser beam, it is possible to achieve a productivity far higher than usual, said surface following a path in such a manner that the area(s) on the article to be processed several times, typically 10-20 times, pass below the laser beam and is(are) thereby repeatedly hit by a short laser pulse at a low efficient frequency. The productivity achieved is even far higher than the productivity achieved by a single pulse drilling in the same material, the latter single pulse drilling resulting in a substantially poorer hole quality, resolidified fuse on the walls of the hole, and often a rather significantly varying hole size, as well as in larger hole diameters.

During the production of a circle of holes on tubes or surfaces, where the article is rotating and the holes are produced by means of a number of pulses in each hole, i.e. one pulse per rotation, the following conditions determine the productivity:

- The diameter of the bore, the diameter of the focusing laser beam and the pulse width.

It is possible to determine a maximally allowable relative peripheral speed in response to the diameter of the holes and the width of each laser pulse. When holes with an inlet diameter of 0.2 mm are to be drilled in steel by means of a laser beam of a focusing diameter of 0.1 mm, and when each laser pulse is of a duration of about 0.05 ms, the maximally allowable peripheral speed is about 1 m/s.

- The pulse frequency of the laser

10 The maximum pulse frequency of the laser determines the shortest interval between two pulses. CO<sub>2</sub> lasers can be pulsed at a maximum frequency of up to 2000-5000 Hz. When the distance between the holes is short, the maximum frequency of the laser sets a limit to the peripheral  
15 speed of the article.

- The maximum drilling frequency of a hole

As previously mentioned one of the recognitions behind the invention is that it is possible to drill holes of high quality by combining short pulses and low repetition  
20 frequencies, which leads to the conclusion that a maximum frequency applies, typically 10-20 Hz, at which a hole can be drilled. The latter sets a limit to the number of revolutions possible for the drilling.

When holes are to be drilled in a tube of stainless steel  
25 of

- |                                  |        |
|----------------------------------|--------|
| - a wall thickness of            | 1 mm   |
| - a diameter of                  | 30 mm  |
| - a hole diameter of             | 0.2 mm |
| - a distance between the holes f | 0.5 mm |

4

by means of a laser emitting

- a pulse width of 50  $\mu$ s
- at a maximum frequency of 2500 Hz
- a beam of a diameter of 0.1 mm

5 and when the following data are to be used per hole

- number of pulses 10
- a maximally efficient frequency of 20 Hz

the following limits are set to:

- peripheral speed 1 m/s
- 10 involving a maximum speed of rotation of 10 r.p.s.
- maximum laser frequencies of 2500 Hz
- as well as holes per rotation approx. 200
- involving a maximum speed of rotation of 12 r.p.s.
- maximally efficient frequency 20 Hz
- 15 involving a maximum speed of rotation of 20 r.p.s.

Thus the peripheral speed of the above example sets a limit to the number of revolutions to 10 r.p.s. As each hole requires 10 pulses, the 200 holes are completed in about 1 s.

20 No other drilling technique exists, not even a technique based on laser, which can produce the above number of holes of such a quality in 1 s. A solid state laser drills approximately 10 holes per s in the same material/thickness but resulting in a larger diameter of the holes.

25 Both a solid state laser and a CO<sub>2</sub> laser can drill the same hole quality at a conventional laser drilling technique at a speed of 0.5-2 holes per s.

Brief Description of the Drawing

The invention is described in greater details below by means of examples of embodiments and with reference to the accompanying drawings, in which

Fig. 1 is a sectional view through an article with a laser drilled row of holes, the centre lines of said holes being radially situated in the article,

#### Best Mode for Carrying Out the Invention

During a laser processing, such as cutting, drilling or

welding, by means of a pulsed laser, a combination of laser pulse and pulse intervals is used during each processing step, whereby the pulse width must be substantially shorter than the pulse interval for the sake of the quality of the processing. In order to increase the productivity without affecting the quality, a simultaneous processing of several articles or article areas is performed, cf. Fig. 1 outlining a drilling of N holes in a row on a cylindrical article 1.

Fig. 1 is a cross-sectional view of an article with a laser drilled row of holes, the centre lines of said holes extending radially in the article 1. Each hole 2 must be processed by a pulse with a large pulse interval simultaneous with the article 1 being continuously turned. A suitable synchronizing device causes the laser to emit a short pulse each time the position of a hole 2 is passed.

The principle of a pulsed fine cutting and welding is exemplified in Fig. 2, where a number of articles 1 are to be welded at a low pulse frequency. The articles 1 are mounted on a rotating device 4, and the welding is performed in the outlined sequence while the device 4 rotates continuously and relatively quickly and simultaneous with the beam being moved rather slowly in the desired pattern.

Fig. 2 is a top view of the articles 1, i.e. from the side where the laser beam is emitted.

While the relative movement is established, the article 1 and/or the focal point of the laser beam can be moved. Thus the relative movement generating each welding geometry of Fig. 2 can be established both by translating the centre line of the rotating device 4 and by displacing the focal point of the laser beam, e.g. by means of movable optical means.

Som laser processings require an amendm nt f the paramet-  
ters during each processing cycle. Such an amendment is  
advantageously performed in the processing sequence de-  
scribed in connection with Fig. 3. An example thereof is  
5 the drilling of a large number of uniform holes in a metal  
wheel, whereby each cycle comprises the steps of first  
drilling a through hole followed by a cutting of the final  
geometry of the hole by cutting from the first hole. The  
drilling of the hole and the following cutting are per-  
10 formed by two different sets of processing parameters,  
i.e. different pulse energies and different gas pressures  
inside the cutting nozzle. The technique described renders  
it possible to complete simultaneously a large number of  
starting holes, whereafter the parameters are changed  
15 before the cutting is performed. In this connection it is  
possible to perform more complicated parameter amendments.

During the processing sequence outlined in Fig. 1, the  
movement of the article is synchronized with the triggering  
of the laser by means of a continuously rotating article  
20 holder 6. The article holder comprises a detecting device  
7, whereby the laser pulse is triggered as outlined in  
Fig. 3, wherein an optocoupler 7 registers each time a  
notch 6" or a hole in a perforated disk passes the holder  
6, said disk being mounted on the rotating article holder.  
25 The optocoupler 7 transmits a signal triggering the laser  
through suitable electronics. The trigger signal can be  
interrupted and transmitted to the laser by means of a  
manual or automatic system, such as a servomechanism. As  
a result, a precisely defined number of rotations are  
30 performed with the laser coupled to the system (N in Figs.  
1 and 2). In addition, the starting up/slowing down of  
the article holder 6 or the insertion/removal of the  
article in and from the continuously rotating article  
holder are performed without causing the laser to emit a  
35 pulse.

The above trigger system can, of course, also be mounted on the shaft of the motor driving the article holder or in a transmission system between the driving motor and the article holder.

5 The synchronizing can furthermore be provided by a control system transmitting signals both to the article-rotating system and to the laser. The latter is for instance rendered possible by an electronic device or a computer generating pulses in such a manner that said pulses control  
10 a step motor. In turn the step motor controls the movement of the article simultaneous with triggering the laser. The control system may in the latter case be such that the step motor can receive a predetermined number of pulses each time the laser is to be triggered one time.

15 Fig. 4 illustrates a moving pattern, according to which the article passes the optical instruments of the laser in a uniform movement while the optical instruments simultaneously perform a uniform movement so as in each pulse moment to reduce or eliminate the relative movement  
20 between the article and the laser beam. Fig. 4 shows a system where the centre line of the laser beam is caused to sweep by a rotating polygonal deflecting mirror 14 while the article 1 rotates, said deflecting mirror 14 being situated in front of a convex lens 9 in the present  
25 embodiment. By synchronizing the rotation of the article with the rotation of the mirror 14 and the emission of laser pulses, it is possible to prevent the focal point of the laser beam from moving relative to the article while each laser pulse is emitted.

30 The invention is illustrated in greater details below by means of the examples.

Laser drilling of polycarbonate articles for heart/lung machines.

The article is shaped as a substantially cylindrical component, where a number of holes are to be used for oxidizing blood. The surface, in which the holes are to be produced, is tubular and of a diameter of about 60 mm.

5 The wall thickness is about 3 mm. 120 holes of a diameter of about 0.22 mm are situated in a plane perpendicular to the axis of the tube. The processing parameters are:

- pulse width: about 50  $\mu$ s
- number of pulses: about 20 per hole
- 10 - number of revolutions: about 5 r.p.s.
- processing period for 120 holes: 4 s.

The article is shown in Figs. 1 and 3.

#### Laser drilling of tubes.

Reference is made to page 4, where rings of holes of about 15 0.2 mm are to be drilled in tubes of a wall thickness of 1 mm and with about 200 holes per ring and one ring per s.

The article and the equipment unit for the production thereof are shown in Fig. 5.

A tube 1 is provided with rows 13 of holes, only one row 20 of holes being produced at a time by the described technique. The pulsed laser beam 2 is focused in a spot on the surface of the article by means of a lens 3. A gas beam is transmitted coaxially to the surface of the article by means of a nozzle 4 in order to remove vapours above the 25 article. The article is rotated by two rotating clamping devices 5 and 6 centering and retaining the tube. A driving means, such as a tandem gear or a tandem wheel 11, rotates the tub and holding devices. A perforated disk 10 is situated on one rotating device, said disk passing through 30 an optocoupler 9. The optocoupler 9 emits a voltage varying

in response to whether light can be transmitted from one side to the other (hole in the perforated disk) or the light from one side of the optocoupler cannot pass to the other side (the perforated disk is shielding). The opto-  
5 coupler is used for triggering a laser pulse passing through a hole in the perforated disk. When a suitable number of revolutions and the processing of a row of holes have been completed, the laser is interrupted and the tube is axially displaced by the clamping device 5 being  
10 opened. Subsequently, the tube is displaced by means of a displacing means 12 optionally driven by a motor. Now the clamping device 5 clamps about the tube and the clamping device 6 is opened, whereafter the displacing means 12 returns to its starting position and the clamping device  
15 6 again clamps about the tube. The tube has now been displaced a short distance and is again rotating whereafter the next row of holes can be drilled. The above cycle continues until the processing has been completed.

#### Laser drilling of holes in a metal disk

20 Instead the holes 13 can be drilled in a circular track in a disk. When the track is of a diameter of 40 mm, all the holes in the track are drilled in about 1.5 s, provided there are less than 375 holes in the track. The article and the equipment unit for the production are shown in  
25 Fig. 6.

In this example, a circular disk 1 has been inserted from the bottom and upwards into a rotating article holder 2 optionally driven by a driving belt 3. The article holder 2 is provided with a perforated disk 4 activating an  
30 optocoupler 5 for the synchronizing of the laser pulses with the number of revolutions. The laser beam 6 is focused by means of a lens 7; and a gas nozzle 8 is situated between the lens 7 and the processing spot, said gas nozzle discharging a gas beam so as to remove material vapours

etc.

Cutting holes in for instance spinner wheels for the production of glass wool.

Large spinner wheels are used for the production of glass wool. The melted glass is poured into a quickly rotating bowl rotating about a vertical axis. Subsequently, the centrifugal force presses the glass out through a number of holes in the vertical cylindrical sides of the bowl.

A spinner wheel comprises about 17,000 holes of a diameter of about 1 mm. The holes are situated at regular intervals of about 2 mm on the cylindrical surface and are arranged in about 30 circular tracks, each track including about 600 holes. The spinner is made of high-strength steel and in the hole section the spinner is of a wall thickness of about 4 mm.

These holes are now drilled either by means of an electron beam, ECM, or by means of a laser. When the holes are drilled by means of a strong ND-YAG-laser pulse per hole, the quality is unlike. If instead a ND-YAG-laser trepanation is used, where the holes are produced by cutting one hole at a time, an improved quality is achieved. Each hole is subjected to the trepanation for about 2 s. Thus the existing technique operates with a production time per spinner of about 10 h.

By the new technique according to the invention the trepanation is to be performed as outlined in Fig. 7. In this embodiment, holes arranged in a circular ring are simultaneously produced during the rotation of the article in such a manner that initially only one beam is transmitted into each hole followed by a second beam into each hole etc. The beam path and the article are displaced relative to one another after each rotation resulting in a cutting

of each hole. Fig. 8 illustrates an equipment unit for producing spinner wheels.

The article 1 to be drilled is rotated by an article holder 6 driven by a motor 7. A perforated disk 8 is mounted on the article holder, and as previously described said disk triggers an optocoupler 9 so as to trigger the laser. The processing is also performed by means of a lens/nozzle system 3, 4 concentrating the laser beam and transmitting a gas beam towards the article. Fig. 8 shows in fact a laser cutting, where the gas beam is of major importance because said beam removes fuse from the cutting groove and co-operates in exothermal reactions with the melted/evaporated material deriving from the laser cutting. The relative cutting movement between the article and the laser beam can be provided by means of an x-y-moving system 5, which may be numerically controlled.

A pulse width of 0.1 ms involves a peripheral speed of about 0.5 m/s, which corresponds to a pulse frequency of 250 Hz. When 80 pulses are used for cutting each hole, the drilling per hole is of a duration of about 0.33 s, which means a total processing period of about 2 h.

#### Laser engraving pressure rollers

In connection with the production of pressure rollers, cf. for instance the previously mentioned German Offenlegungsschrift, it is possible to improve the quality of the holes by producing each hole by means of several pulses at a low frequency. Compared to the previous examples, such an engraving technique requires shorter laser pulses: either Q-switched lasers (ND-YAG- or CO<sub>2</sub> lasers) operating with pulse widths in the range of 0.1-10  $\mu$ s, or the more short-pulsed lasers (TEA or excimer lasers) typically emitting pulses in the range of 10-100 ns. The depth per pulse in a hole is more or less proportional to the pulse

width, and the short-pulsed lasers provide the best results. Several pulses are, however, required per hole which means more revolutions for the production of a ring of holes.

- 5 The basic structure of the article and the equipment for the production thereof are shown in Fig. 9.

A pressure roller 6 is situated on two bearings 7, 8 driven by a motor 12 through a holding device (claw/centering cartridge) 9. In this case too a perforated disk 10 and  
10 an optocoupler 11 are involved. An optical slide 1 can be displaced along the axis of the pressure roller 6. The optical slide comprises a deflection mirror 2 deflecting the laser beam 3 through the lens 4 and the nozzle 5 in such a manner that the laser beam 3 is focused on the  
15 surface of the article. One track at a time is completed on the pressure roller 6, whereafter the slide 1 is displaced and an additional track is produced. The holes in the pressure roller are typically 10-100  $\mu\text{m}$  deep, and the number of holes per cm in the axial and tangential  
20 direction is typically between 50 and 300.

#### General remarks concerning triggering

Triggering can also be performed by means of other devices beyond perforated disks/optocouplers, such as for instance by means of a surge generator controlling both a step  
25 motor and the laser.

The trigger signals of Fig. 10 can be used regardless of the triggering method.

A continuously rotating perforated disk triggers an optocoupler so as to transmit a signal 1. The system controlling the processing can then transmit a primary gating  
30 signal 2 for a suitable period, such as a predetermined

number of revolutions. Subsequently, when permitted by the primary gate 2, the laser emits pulses 3 synchronously with 1.

The width of the laser pulse may be as 4. A local gating 5 can, however, set a minimum period before the next pulse can be emitted, which results in laser pulses with a longer interval 6. The latter procedure is rendered possible by electronically selecting different number of holes.

In certain situations, such as when engraving pressure 10 rollers, it is preferred to include an additional triggering 7, for instance for each rotation, so as to ensure a varying pattern described below. Instead of a gating over several rotations, a control system, such as a computer, can generate information on a combined gating when some 15 patterns are desired to be generated in form of on/off for a pulse 8, or in form of varying pulse sizes per triggering 9.

It is also possible to perform several rotations, where the number of spots to be struck varies so as for instance 20 to generate varying hole depths, cf. 10a-d.

Claims:

1. A method of processing one or more articles by means of a pulsed laser beam, whereby the processing is performed in several steps, c h a r a c t e r i s e d in that after  
5 each processing step the laser beam is displaced relative to the article so as to allow the performance of the following processing step in a successive processing area, the processing sequence being recommenced and repeated until the desired processing in each processing area has  
10 been completed.
2. A method as claimed in claim 1, c h a r a c t e r i s e d in that the pulse width is substantially shorter than the pulse interval.
3. A method as claimed in claim 1 or 2, c h a r a c -  
15 t e r i s e d by a relative movement between the article and the laser beam during the pulsing and the pulse interval.
4. A method as claimed in claim 1 or 2, c h a r a c -  
t e r i s e d in that during each laser pulse the laser  
20 beam follows the surface of the article by a simultaneous movement of the laser beam and the article.
5. A method as claimed in one or more of the preceding claims, c h a r a c t e r i s e d by the article rotating at a uniform speed during the processing.
- 25 6. A method as claimed in one or more of the preceding claims for drilling holes, c h a r a c t e r i s e d in that the pulse emission of the laser beam is synchronized with the relative m v m e n t of the article in such a manner that during each f t h f l l o w i n g pulse sequences th laser  
30 beam hits the sam row of spots on the article.
